(Dated: July 28, 2009)

The spectrum and scale of fluctuations in protein structures affect the range of cell phenomena, including stability of protein structures or their fragments, allosteric transitions and energy transfer. The study presents a statistical-thermodynamic analysis of relationship between the sequence composition and the distribution of residue fluctuations in protein-protein complexes. A one-node-per-residue elastic network model accounting for the nonhomogeneous protein mass distribution and the inter-atomic interactions through the renormalized inter-residue potential is developed. Two factors, a protein mass distribution and a residue environment, were found to determine the scale of residue fluctuations. Surface residues undergo larger fluctuations than core residues, showing agreement with experimental observations. Ranking residues over the normalized scale of fluctuations yields a distinct classification of amino acids into three groups: (i) highly fluctuating - Gly, Ala, Ser, Pro and Asp, (ii) moderately fluctuating - Thr, Asn, Gln, Lys, Glu, Arg, Val and Cys (iii) weakly fluctuating - Ile, Leu, Met, Phe, Tyr, Trp and His. The structural instability in proteins possibly relates to the high content of the highly fluctuating residues and a deficiency of the weakly fluctuating residues in irregular secondary structure elements (loops), chameleon sequences and disordered proteins. Strong correlation between residue fluctuations and the sequence composition of protein loops supports this hypothesis. Comparing fluctuations of binding site residues (interface residues) with other surface residues shows that, on average, the interface is more rigid than the rest of the protein surface and Gly, Ala, Ser, Cys, Leu and Trp have a propensity to form more stable docking patches on the interface. The findings have broad implications for understanding mechanisms of protein association and stability of protein structures.

Keywords: structural fluctuations, elastic network models, protein stability, protein-protein interactions, amino acid propensities

I. INTRODUCTION

A remarkable difference between sequence compositions of regular and irregular secondary structure elements of proteins has been attracting considerable attention for more than 30 years [1, 2, 3, 4, 5, 6]. Amino-acid composition profiles revealed that the irregular regions (protein loops) are enriched in Gly, Pro, Ser and Asp. The regular regions (α – helices and β – strands) contain less of these amino acids. Helices are enriched in Leu, Ala, Glu and Gln, and β – strands are enriched in Val, Ile, Phe and Tyr. Amino-acid compositions of protein interfaces has been analyzed [7, 8, 9, 10]. Despite the extensive use of the statistics in almost all aspects of protein modeling (e.g. in computational algorithms for the secondary structure assignments (see [11] for the review); in knowledge-based approaches to predict protein structures [12, 13, 14, 15, 16, 17], in receptor-ligand docking [18, 19, 20]) the understanding of mechanisms that form amino acids propensities is still incomplete and poses a challenge for researchers in physics and biology. Recent discoveries of chameleon sequences, that un-

dergo helix-sheet transitions [21, 22, 23, 24, 25, 26], and intrinsically disordered proteins or fragments, that undergo order-disorder transitions [27, 28, 29], have added interest to the problem. Studying the distribution, the scale and features of structural and thermal fluctuations in proteins is one way to tackle this puzzle.

Protein functionality, encoded into the sequence, is based on a dual ability of proteins to sustain and change their structures [30]. The relationship has different degrees of sensitivity to the location and the scale of changes of protein structures (e.g. CH_3 group rotations, conversions of side-chain rotamers, cis-trans isomerization of proline or domain shifts). Last ten years demonstrated increasing popularity of low-resolution or coarse-grained models in conjunction with harmonic potentials, called elastic network models (ENM), for deciphering and modeling various large-scale structural changes (e.g., allosteric changes in protein structures [31, 32, 33, 34], structural changes on transition pathways [32, 35, 36, 37, 38, 39, 40], global conformational changes upon protein-protein binding [41, 42, 43]). Other applications of these models include the analysis of Debye-Waller factors of C_α atoms [31, 44, 45, 46, 47, 48, 49] and protein docking [42, 50].

Two types of ENMs are widely used: homogeneous and nonhomogeneous models. A homogeneous ENM is a network of nodes represented by C_α atoms and con-

*Electronic address: ruvinisky@ku.edu

†Electronic address: vakser@ku.edu

nected by Hooke springs if the distance between nodes is less than a cutoff radius [31, 32, 38, 39, 40, 41, 43, 44, 45]. All network nodes are assigned an equal mass that smoothes protein mass density. The homogeneous ENM has two parameters only, the cutoff radius and the spring force constant. Nonhomogeneous ENMs introduce structural and interaction inhomogeneity by assigning residue masses to the network nodes represented by C_α atoms [48] or by assigning distance- or residue type-dependent force constants to interacting nodes [34, 35, 37, 47, 48, 49, 50]. The effect of protein sequence variations on the spring force constants has been considered recently [33]. Double-well ENMs are used to model large-scale conformational transition pathways [37, 39, 40, 51]. Merging residues into rigid blocks is used to consider properties of large macromolecules within ENM of a lower resolution [32, 38, 46, 52]. Less “extreme” coarse graining keeps three translational degrees of freedom of C_α -based nodes and degrees of freedom of bond angles and dihedrals (see [51, 53, 54]).

In the context of nonhomogeneous ENMs, we present a novel method to account for the protein mass distribution and inter-atomic contacts within the coarse-grained model. We move network nodes from C_α atoms to the centers of mass of protein residues to bring in the effects of side chains into the model. We derive a modified Tirion-like potential [55] to bring in structural details of the atomic level and put forward a statistical-thermodynamic formalism to calculate residue fluctuations of a set of protein complexes [56]. We show that the scale of residue fluctuations increases from the inside to the protein surface, showing agreement with the Frauenfelder-Petsko-Tsernoglou model [62]. We suggest a classification of protein residues based on the normalized scale of fluctuations and discuss how the scale of fluctuations correlates with amino acid propensities in secondary structure elements, chameleon sequences and disordered fragments. Fluctuations of binding site residues (interface residues) are compared with other surface residues. The tendency of some residues to form more stable docking patches on the interface is discussed as well as the role of loops at early stages of protein thermal denaturation.

II. MODEL

A modified nonhomogeneous ENM is used in calculations. Network nodes are placed in the centers of mass of protein residues and residue masses are assigned to the corresponding network nodes. The following is a description of a formalism to consistently transform the inter-atomic protein energy landscape into the inter-residue landscape. As a result, we obtain a modified inter-residue harmonic potential with a spring force constant proportional to the number of inter-atomic contacts between residues (see Eq (3) below).

The interaction energy between protein residues i and

k is

$$U_{ik}(\mathbf{R}_i - \mathbf{R}_k) = \sum_{\alpha, \beta} U_{\alpha\beta}(\mathbf{R}_i + \mathbf{u}_\alpha^i - \mathbf{R}_k - \mathbf{u}_\beta^k), \quad (1)$$

where $\mathbf{R}_{i,k}$ are radius vectors of the centers of mass of residues i and k , $\mathbf{u}_{\alpha,\beta}^{i,k}$ are the radius vectors of atoms α and β relative to the centers of mass of the residues i and k accordingly. The sum in Eq. (1) runs over all pairs of atoms separated by a distance less than the interaction cutoff. We use the cutoff of 14 Å that assures a tolerable level of the cutoff-related ruggedness of the energy landscape [57, 58]. Introducing a residue-residue potential, one can rewrite Eq. (1) as $U_{ik}(\mathbf{R}_i - \mathbf{R}_k) = N_{ik}V(\mathbf{R}_i - \mathbf{R}_k)$, where N_{ik} is a number of inter-atomic interactions between residues i and k and V is the coarse-grained or inter-residue potential *per se*. Assuming that inter-residue interactions are in equilibrium in a native protein and using a Lennard-Jones form of the inter-residue potential, we can expand $V(\mathbf{R}_i - \mathbf{R}_k)$ in Taylor series of deviations $R_{ik} - R_{ik}^0$ of the inter-residue distance $R_{ik} = |\mathbf{R}_i - \mathbf{R}_k|$ from its equilibrium R_{ij}^0 . Expanding to the second order in $R_{ij} - R_{ij}^0$ yields

$$U_{ik}(\mathbf{R}_i - \mathbf{R}_k) = -N_{ik}\varepsilon + 36N_{ik}\varepsilon \left(\frac{R_{ik} - R_{ik}^0}{R_{ik}^0} \right)^2, \quad (2)$$

where ε is the depth of the Lennard-Jones potential. Eq. 2 shows that inter-residue interactions are proportional to the number of inter-atomic interactions and decrease with the increase of the inter-residue distance as $1/(R_{ik}^0)^2$.

Since $\mathbf{R}_{i,k} = \mathbf{R}_{i,k}^0 + \mathbf{r}_{i,k}$, we obtain

$$U_{ik}(\mathbf{r}_i - \mathbf{r}_k, \mathbf{R}_{ik}^0) = -\varepsilon N_{ik} + 36\varepsilon \frac{N_{ik}}{(R_{ik}^0)^2} \left(\frac{\mathbf{R}_{ik}^0}{R_{ik}^0} (\mathbf{r}_i - \mathbf{r}_k) \right)^2, \quad (3)$$

where $\mathbf{r}_{i,k}$ are the deviations of the residue centers of mass from its equilibrium position. The main difference between Eq (3) and Tirion-like potentials [55] used in nonhomogeneous ENMs is the factor N_{ik} which introduces the distribution of inter-atomic interactions into the coarse-grained model. In other words, the change of the protein model resolution from the atomic to the residue level results in the appearance of this factor in the inter-residue potential.

The protein Lagrangian

$$\mathcal{L} = \sum_{i,k=1}^N \frac{m_i}{2} (\dot{\mathbf{r}}_i)^2 - U_{ik}(\mathbf{r}_i - \mathbf{r}_k, \mathbf{R}_{ik}^0) \quad (4)$$

derives the following $3N$ equations of motions

$$m_i \ddot{\mathbf{r}}_i = - \sum_{k=1}^N C_{ik} (\boldsymbol{\alpha}_{ik} (\mathbf{r}_i - \mathbf{r}_k)) \boldsymbol{\alpha}_{ik}, \quad (5)$$

where m_i is the mass of the residue i , $\boldsymbol{\alpha}_{ik} = \mathbf{R}_{ik}^0 / R_{ik}^0$, $C_{ik} = 72\varepsilon N_{ik} / (R_{ik}^0)^2$ and N is the number of protein

residues. As usual, we seek an oscillatory solution of the form $\mathbf{r}_k = \mathbf{A}_k \exp(i\omega t)$, where $\mathbf{A}_k$ are some amplitude factors to be determined. The substitution of the trial solution into the equations of motions leads to the eigenvalue problem $(\mathbf{H} - \omega^2 \mathbf{I})\mathbf{A} = 0$, where $\mathbf{A} = \{A_1^x, A_1^y, A_1^z, A_2^x, A_2^y, \dots\}$ is a $3N$ column vector of the amplitude factors, $\mathbf{I}$ is a $3N \times 3N$ unit matrix, $\mathbf{H}$ is a $3N \times 3N$ matrix composed of 3×3 super elements

$$H_{ik}(i \neq k) = \begin{bmatrix} h_{ik}^{xx} & h_{ik}^{yx} & h_{ik}^{zx} \\ h_{ik}^{xy} & h_{ik}^{yy} & h_{ik}^{zy} \\ h_{ik}^{xz} & h_{ik}^{yz} & h_{ik}^{zz} \end{bmatrix}, H_{ii} = - \sum_k' H_{ik}, \quad (6)$$

where $h_{ik}^{ab} = -C_{ik}\alpha_{ik}^a\alpha_{ik}^b/m_i$ and the upper indexes a, b stand for x, y, z projections of the vector α_{ik} .

The prime in sums over k in Eqs. (6) means that a term $i = k$ is not accounted for. We use our program AH (**A**nalyzer of **H**armonics) to find protein eigenfrequencies $\{\omega\}$ and normalized eigenvectors. The k th oscillation can be written in the form

$$x_k = \sum_{i=1}^{3N-6} G_{ki} c_i \exp(\omega_i t) = \sum_{i=1}^{3N-6} G_{ki} \Theta_i, \quad (7)$$

where $\Theta_i = \text{Re}[c_i \exp(\omega_i t)]$ is the so called normal coordinate, Re stands for ‘‘real part of,’’ c_i is a constant determined by initial conditions, columns of the matrix $\mathbf{G}$ are the normalized eigenvectors. The normal modes are described by

$$\mathcal{H} = \sum_{i=1}^{3N-6} \frac{M_i}{2} (\dot{\Theta}_i^2 + \omega_i^2 \Theta_i^2), \quad (8)$$

where $M_i = \sum_{k=1}^{3N-6} m_k G_{ki}^2$ is the effective mass of the i th normal mode [59]. Note that for a homogeneous ENM, m_i is a constant equal to some parameter m and, therefore, all modes will have equal effective masses: $M_i = \sum_{k=1}^{3N-6} m G_{ki}^2 = m$.

The mean-square fluctuation of the k th residue along the coordinate axis x is $\langle x_{kx}^2 \rangle = \sum_{ij} G_{kxi} G_{kxj} \langle \Theta_i \Theta_j \rangle$, where the angular brackets denote a Boltzmann average with the Hamiltonian (8) over the normal modes, $k_{x,y,z}$ are the numbers of degrees of freedom associated with the residue center of mass oscillations along the coordinate axes x, y, z . Boltzmann averaging of pair products $\langle \Theta_i \Theta_j \rangle$ of normal coordinates yields $\langle \Theta_i \Theta_j \rangle = \delta_{ij} T k_B / (M_i \omega_i^2)$, where T is the temperature, k_B is the Boltzmann constant and δ_{ij} is the Kronecker delta ($\delta_{ij} = 1$ if $i = j$ and $\delta_{ij} = 0$ if $i \neq j$). The total mean-square fluctuation of the k th residue has the form

$$\langle \mathbf{r}_k^2 \rangle = T k_B \sum_{i=1}^{3N-6} \frac{G_{kxi}^2 + G_{kyi}^2 + G_{kzi}^2}{M_i \omega_i^2} \quad (9)$$

It is important to note that the residue fluctuation, derived in Eq (9), shows nonlocal dependence on the mass distribution in a protein. This effect totally disappears in the framework of a homogeneous ENM.

Removing the effect of the parameter ε on residue fluctuations, we introduce a mobility ratio (MR) of the k th residue in the form

$$\mathcal{R}_k = \frac{\langle \mathbf{r}_k^2 \rangle}{\mathbf{r}_{av}^2}, \quad (10)$$

where $\mathbf{r}_{av}^2 = \sum_{k=1}^N \langle \mathbf{r}_k^2 \rangle / N$ is the averaged mean-square fluctuation in a protein.

We computed the mobility ratios for each of the protein residues in 184 proteins from the 92 non-obligate protein-protein complexes selected from a docking benchmark set [56]. For each of the proteins MRs were grouped in twenty groups according to names of standard amino acids and twenty average MRs were computed. The obtained values were averaged over the set of 184 protein structures. Figures 1-3 show mean MRs and standard deviations of the mean.

III. RESULTS

The results show that large equilibrium fluctuations ($\mathcal{R} \geq 1$) of protein structures are associated with the oscillations of the center of mass of Gly, Ala, Ser, Pro and Asp (Group I) which are the most lightweight residues with the exception of Asp (Fig. 1). Modest fluctuations ($\mathcal{R} = 0.7 \div 1.0$; Group II) are associated with six polar residues (Thr, Asn, Gln, Lys, Glu, Arg) and two nonpolar residues (Val, Cys). The small fluctuations ($\mathcal{R} = 0.3 \div 0.7$; Group III) are associated with six nonpolar residues (Ile, Leu, Met, Phe, Trp) and polar residues His and Tyr. It is interesting to note that, with regards to hydrophilicity, groups I, II and III can be characterized as mixed, mostly polar and mostly nonpolar.

Analysis of the scale of fluctuations of surface and core residues shows that on average all surface residues demonstrate larger fluctuations than core residues (Fig. 2). Surface (core) residues are defined here as those residues which have relative solvent accessible surface area higher(lower) than 25% and are identified using NACCESS [60]. The difference is readily explained by the difference in numbers of nearest neighbors of surface and core residues (the environment effect). In comparison with core residues, surface residues have less nearest neighbors [61]. Therefore, they are less restricted and experience larger fluctuations. First reports of this effect go back to crystallographic studies of myoglobin [62, 63] and lysozyme [64]. It has been showed that atomic mean-square displacements increase from the protein core to the protein surface. Frauenfelder *et al* [62] suggested that, in general, proteins have a condensed core and a semi-liquid surface.

FIG. 1: The mobility ratios of protein residues arranged in the order of increasing mass.

The same environment effect appears as a small root mean-squared deviation between bound and unbound states of pocket side chains [65] or as a decreased number of rotamers allowable for buried amino acids in comparison with surface amino acids [66, 67]. This also clears up a seemingly striking difference in hydrophilicity found between residues of groups II and III. Indeed, amino acid residues are distributed nonhomogeneously in proteins. Polar residues prefer surface positions, but unpolar residues are more often found in a protein core. That is why the mostly polar group II demonstrates higher mobility ratios than the mostly unpolar group III. On the other side, high mobility ratios of nonpolar residues Gly and Ala suggest that the environment effect is not the only factor. The amplitude of fluctuations is inversely proportional to the effective amino acid masses (see Eq. 9). As a result, the largest fluctuations are associated with Gly and Ala, the most lightweight residues, but the smallest fluctuations are associated with Tyr and Trp, the most heavy residues (Fig. 1).

Comparing fluctuations of binding site (interface) residues with other surface residues, we found that although, on average, interface is less mobile than the rest of the protein surface (Fig. 3), the noticeable difference ($\mathcal{R}_j^{sur} - \mathcal{R}_j^{int} > 0.25$, $\mathcal{R}_j^{int,sur}$ is the mobility ratio of the interface or other surface residue j) relates to Gly, Ala, Ser, Cys, Leu and Trp. Four of these residues (Gly, Ala, Leu and Ser) are the most common residues at protein interfaces, and residues Cys and Trp are the most infrequent interface residues [7, 8]. The most conserved interface residue Trp [9] also is the most stable one (see Fig. 3). Two other highly conserved interface residues (Met and Phe) [9] demonstrate decreased mobility in binding sites to a lesser extent. Note that the difference between bind-

FIG. 2: The mobility ratios of surface and core protein residues. Surface (core) residues are defined here as those residues which have relative solvent accessible surface area higher(lower) than 25%.

ing cites and the rest of the protein surface relates mainly to fluctuations of the nonpolar residues with the exception of Ser, a polar residue. These results are in agreement with the experimental observation of reduced fluctuations in binding sites of myoglobin [69] and bacteriorhodopsin [68] in comparison with fluctuations of the rest of macromolecules. Frauenfelder and McMahon [69] also noted that the four (Leu29, Phe43, Val68 and Ile107) of the six residues with reduced fluctuations surrounding the oxygen molecule are nonpolar. The two other residues are His64 and His93 ($\mathcal{R}_{His}^{sur} - \mathcal{R}_{His}^{int} = 0.16$). The solvent-mediated attraction between nonpolar residues of a receptor and a ligand results in the hydrophobic contribution to binding free energy, which is considered to be one of major factors stabilizing protein-protein complexes [70, 71, 72, 73]. We suppose that Gly, Ala, Ser, Cys, Leu and Trp form low-mobility surface “pads” that constitute a “landing ground” for binding proteins.

The larger ability to fluctuate of Group I residues provides an insight into the inability of sequences abundant in Gly, Ala, Ser, Pro and Asp to fold into regular protein secondary structure elements (α – helices or β – strands). High mobility prevents the formation of long-range order thus contributing to irregular protein secondary structure elements (loops). We computed the correlation coefficient between the mobility ratios and corresponding percentages of amino acid residues in the bank of loops [5] (see Fig. 4)). The analysis showed significant relation with 0.9 correlation coefficient.

We suggest that the same reasoning explains features of amino acid distributions observed in chameleon sequences [21, 22, 24, 26] and disordered proteins [28, 29].

FIG. 3: The mobility ratios of interface and non-interface surface protein residues.

Indeed, highly and moderately fluctuating amino acid residues (in particular, Gly, Ala, Ser, Glu and Lys) are abundant in disordered and “dual personality” protein fragments, whereas the residues with the low mobility ratio (e.g. Tyr, Trp, Phe, Ile) are rarely found there [28, 29].

Statistics of protein residues in chameleon sequences shows that Ala, Ile, Leu and Val are the most frequent residues in chameleon sequences [22, 26]. Since only Ala belongs to the Group I of highly fluctuating residues (Fig. 1), we can hypothesize that an instability driving helix $\leftrightarrow$ sheet transitions may often originate at Ala residues if the other highly fluctuating residues are absent. Frequencies of occurrence of Gly and Ser residues increase with the increase of the length of the sequence [22]. Thus, in general, chameleon sequences may have several islands of instability. Exciting these islands locally (e.g., by mutations that change interactions of the islands with the rest of the protein or by ligands bound in the vicinity of the chameleon sequence), one could trigger a helix $\leftrightarrow$ sheet transition. Mutations of a chameleon sequence, that change the mobility ratio of a sequence position significantly, can also provoke such transitions. It has been reported that a single mutation from Pro to Ala ($\mathcal{R}_{Ala} - \mathcal{R}_{Pro} = 0.4$) converts a β - sheet into an α - helix [23]. Mutations of two consecutive residues from Phe28Phe29 to Pro28Ile29 ($\mathcal{R}_{Pro} - \mathcal{R}_{Phe} = 0.7$, $\mathcal{R}_{Ile} - \mathcal{R}_{Phe} = 0.2$) converts an α - helix into a β - sheet [25].

The mobility ratio derived by Eq (9) increases with the temperature increase. Therefore, we could expect that at the very early stages of protein thermal denaturation amino acid residues of the enhanced ability to fluctuate (Group I) and their structural neighbors will

FIG. 4: The mobility ratios of protein residues against their percentage compositions in protein loops [5].

form first seeds of the unfolded phase. Since the majority of Group I amino acids (Gly, Ser, Pro and Asp) shows higher propensities for loops than for helices or sheets [6], it is possible that the nucleation of the unfolded phase starts on protein loops. Due to the increased ability to fluctuate, Group I residues can be also involved more often than other residues into equilibrium local folding-unfolding reactions scattered over the protein surface [74, 75].

IV. CONCLUSIONS

The current work focuses on the fundamental relationship between the protein sequence, ability to fluctuate and functionality of protein structures. We have considered the relationship within a framework of a novel elastic network model that allows accounting for the distribution of inter-atomic interactions within a coarse-grained approach. The model modifies a commonly used form of the Tirion potential with a spring constant proportional to the number of inter-atomic contacts between residues. We demonstrated that two factors, a protein mass distribution and a residue environment, determine the scale of fluctuations. Surface residues undergo larger fluctuations than core residues in agreement with experimental observations [62, 63, 64]. On average, the protein interface is less mobile than the rest of the protein surface and contains low-mobility pads associated mainly with nonpolar residues. We hypothesize that the conformational instability of protein loops, chameleon sequences and disordered proteins relates to the high content of highly mobile residues and the lack of weakly fluctuating residues. The results show high correlation between fluctuations and the sequence composition of protein loops. Analysis of residue fluctuations and their propensities in

secondary structure elements allows one to conclude that upon thermal denaturation the nucleation of the unfolded phase proceeds from protein loops. The results provide insight into structural fluctuations of proteins and facilitate better understanding of protein association mechanisms.
